The Transfer Matrix in Four-dimensional Causal Dynamical Triangulations

Andrzej Görlich

Abstract Causal Dynamical Triangulations (CDT) is a background independent approach to quantum gravity. In this paper we introduce a phenomenological transfer matrix model, where at each time step a reduced set of quantum states is used. The states are solely characterized by the discretized spatial volume. Using Monte Carlo simulations we determine the effective transfer matrix elements and extract the effective action for the scale factor. In this framework no degrees of freedom are frozen, however, the obtained action agrees with the minisuperspace model.

1 Introduction

The model of Causal Dynamical Triangulations (CDT) was proposed some years ago by J. Ambjørn, J. Jurkiewicz and R. Loll with the aim of defining a lattice formulation of quantum gravity from first principles [1, 2]. The foundation of this model is the formalism of path-integrals applied to quantize a theory of gravitation. The quantum gravity path integral is regularized by discretizing the spacetime geometry $g$ with piecewise linear manifold $\mathcal{I}$. The building blocks of four dimensional CDT are four-simplices, which properly glued along their faces form a simplicial manifold.

An important assumption of CDT is the causality condition. As a consequence of the original Lorentzian signature of spacetime, only causal geometries should contribute to the integral. We will consider globally hyperbolic pseudo-Riemannian manifolds which allow introducing a global proper-time foliation. The leaves of the foliation are spatial three-dimensional Cauchy surfaces called slices. Because topology changes of the spatial slices are often associated with causality violation, we forbid the topology of the leaves to alter in time. For simplicity, we chose the spatial
slices to have a fixed topology of a three-sphere, and establish periodic boundary conditions in the time direction. Therefore, the spacetime topology is $\mathcal{M} = S^1 \times S^3$. Spatial slices of a triangulation are enumerated by a discrete time coordinate $t$. Such a time coordinate is assigned to each vertex of the triangulation, bringing on a distinction between space-like links of length $a_s$ and time-like links of length $a_t$. Because each simplex contains vertices lying in two consecutive spatial slices, there are two kinds of simplices: first of a type $\{4,1\}$ with four vertices lying in one spatial slice and one in the neighboring slice, and second of a type $\{3,2\}$ with three vertices lying in one spatial slice and two in the adjacent slice. The Wick rotation is performed by the analytic continuation to imaginary lengths of the time-like links $a_t \rightarrow iat$. The regularized partition function $Z$ is now written as a sum over causal triangulations $\mathcal{T}$,

$$Z = \int D[g] e^{iS_{\text{EH}}[g]} \rightarrow \sum_{\mathcal{T}} e^{-S[\mathcal{T}]}.$$  \hspace{1cm} (1)

The Einstein-Hilbert action $S_{\text{EH}}[g] = \frac{1}{16\pi G} \int dt \int d^3x \sqrt{-g} (R - 2\Lambda)$ evaluated on a simplicial manifold $\mathcal{T}$ composed of $N_4$ simplices, among them $N_{41}$ being of type $\{4,1\}$, and $N_0$ vertices, gives the discrete Regge action,

$$S[\mathcal{T}] = -K_0 N_0 + K_4 N_4 + \Delta (N_{41} - 6N_0),$$ \hspace{1cm} (2)

where $K_0$, $K_4$ and $\Delta$ are bare coupling constants, and naively they are functions of $G, \Lambda$ and $a_t, a_s$.

We applied Monte Carlo techniques, and using the Regge action (2), measured expectation values of observables within the CDT framework. The simplest observable is the scale factor $a(t)$, or more conveniently the three-volume $n_t$ defined as the number of tetrahedra building slice $t$.

For a certain range of the coupling constants, a typical configuration is bell-shaped, with the average volume profile $\langle n_t \rangle \propto \cos^3(t/B)$. The emerged background geometry behaves like a well defined four-dimensional manifold and is perfectly consistent with a Euclidean de Sitter universe, the classical vacuum solution of a spatially homogeneous and isotropic minisuperspace model \cite{3}. In earlier work we have shown \cite{4} that the discretized minisuperspace action,

$$S[n_t] = \frac{1}{\mathcal{T}} \sum_{t} \left( \frac{(n_{t+1} - n_t)^2}{n_{t+1} + n_t} + \mu n_t^{1/3} - \lambda n_t \right),$$ \hspace{1cm} (3)

describes well not only the measured $\langle n_t \rangle$ but also the fluctuations

$$C_{n_t'} = \langle (n_t - \langle n_t \rangle)(n_{t'} - \langle n_{t'} \rangle) \rangle.$$ \hspace{1cm} (4)

The effective action (3) couples only adjacent slices. Such form suggests that there exists an effective transfer matrix labeled only by the scale factor.
2 The transfer matrix

The model of Causal Dynamical Triangulations is completely determined by a transfer matrix $M$ labeled by three-dimensional triangulations $\mathcal{T}$. The matrix element $\langle \mathcal{T}_1 | M | \mathcal{T}_2 \rangle$ denotes the transition amplitude in one time step between states corresponding to triangulations $\mathcal{T}_1$ and $\mathcal{T}_2$. It is given by the sum over all four-dimensional triangulations $\mathcal{T}$ of a slab, with boundary triangulations $\mathcal{T}_1$ and $\mathcal{T}_2$:

$$\langle \mathcal{T}_1 | M | \mathcal{T}_2 \rangle = \sum_{\mathcal{T} | \mathcal{T}_1, \mathcal{T}_2} e^{-S(\mathcal{T})}.$$

The transfer matrix $M$ depends both on the entropy factor, which counts the number of triangulations $\mathcal{T}$ connecting the boundaries in one time step, and the Regge action $S(\mathcal{T})$. The partition function (1) corresponding to $T$ time steps is then expressed in terms of the matrix $M$,

$$Z = \sum_{\mathcal{T}} e^{-S(\mathcal{T})} = \text{Tr} M^T. \quad (5)$$

The probability of finding a configuration with $T$ spatial slices given by three-dimensional triangulations $\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_T$ is

$$P(T) (\mathcal{T}_1, \ldots, \mathcal{T}_T) = \frac{1}{Z} \langle \mathcal{T}_1 | M | \mathcal{T}_2 \rangle \langle \mathcal{T}_2 | M | \mathcal{T}_3 \rangle \ldots \langle \mathcal{T}_T | M | \mathcal{T}_1 \rangle. \quad (6)$$

We used partition function (5) in Monte Carlo simulations. The measurements performed so far, have been concentrated on the measurement of the three-volume $n_t$. The probability $P(T) (n_1, \ldots, n_T)$ of finding a configuration with spatial volumes $n_1, n_2, \ldots, n_T$ is given by a proper sum of partial probabilities (6). Let $T_3(n)$ denote the subset of three-dimensional triangulations which are built of exactly $n$ three-simplices. We use the projection operator $\rho(n) \equiv |n\rangle \langle n|$ on the subspace spanned by $T_3(n)$,

$$\rho(n) \equiv |n\rangle \langle n| = \sum_{\mathcal{T} \in T_3(n)} |\mathcal{T}\rangle \langle \mathcal{T}|. \quad (7)$$

to express the probability $P(T) (n_1, \ldots, n_T)$,

$$P(T) (n_1, \ldots, n_T) = \frac{1}{Z} \text{Tr} \left[ |n_1\rangle \langle n_1| \cdot M |n_2\rangle \langle n_2| \cdot M |n_3\rangle \ldots \cdot M |n_T| \right]. \quad (8)$$

In (8) it is misleading to think of the aggregated “state” $|n\rangle$ as a normalized sum of the vectors $|\mathcal{T}\rangle$, $\mathcal{T} \in T_3(n)$. Such a vector would again be a single vector located in the space spanned by the $|\mathcal{T}\rangle$’s. It is more appropriate to interpret the “state” associated with $n$ as arising from a classical uniform probability distribution of states $|\mathcal{T}\rangle$ and in this way to treat $\rho(n)$ as the associated density operator.

As mentioned in the Introduction, the form of the effective action (3) obtained from the covariance matrix (4) suggests that there exists an effective transfer matrix $|n\rangle M |m\rangle$ whose elements are labeled by the three-volumes and that it is possible to
effectively decompose observed distributions $P^{(T)}(n_1, \ldots, n_T)$ into a product

$$P^{(T)}(n_1, \ldots, n_T) = \frac{1}{Z} \langle n_1 | M | n_2 \rangle \langle n_2 | M | n_3 \rangle \cdots \langle n_T | M | n_1 \rangle. \quad (9)$$

The effective transfer matrix $M$ depends only on the coupling constants $K_0$, $\Delta$ and $K_4$ but not on the number of slices $T$. In analogy to (6), the elements of the effective transfer matrix correspond to transition amplitudes in one time step between states of a given three-volume.

3 Measurements

In the following, we will assume that we can work with an effective transfer matrix $\langle n | M | m \rangle$ and will show that equation (9) provides a very good approximation of measured data [5].

For simplicity, let us define the two-point function,

$$P^{(T)}(n_t, n_{t+\Delta t}) = \frac{1}{Z} \langle n_t | M^\Delta t | n_{t+\Delta t} \rangle \langle n_{t+\Delta t} | M^{T-\Delta t} | n_t \rangle \quad (10)$$

by summing (9) over all three-volumes except for times $t$ and $t + \Delta t$. The simplest way to measure the matrix elements $\langle n | M | m \rangle$, up to a normalization, is to consider $T = 2$,

$$\langle n | M | m \rangle \propto \sqrt{P^{(2)}(n_1 = n, n_2 = m)}.$$

The effective transfer matrix elements can be measured in various ways. In particular, as follows from (10) for $T = 3, 4$, we have

$$\langle n | M | m \rangle \propto \frac{P^{(3)}(n_1 = n, n_2 = m)}{\sqrt{P^{(4)}(n_1 = n, n_3 = m)}} \quad (11)$$

We tested, that the elements $\langle n | M | m \rangle$ measured in different ways completely agreed up to numerical noise, supporting validity of equation (9). For technical reasons, most measurements were performed using expression (11).

The coupling constant $K_4$ in (2) plays a role of a cosmological constant. To correctly perform simulations, we have to approach with $K_4$ very close to its critical value $K_{4,\text{crit}}$. To efficiently probe the desired range of the three-volume, we added to the Regge action (2) a quadratic term to fix $n_t$ around $n_{\text{vol}}$,

$$S \rightarrow S + \varepsilon \sum_t (n_t - n_{\text{vol}})^2.$$

Because it is consistent with the decomposition (9), its effect can be easily canceled. For technical reasons, we measured the transfer matrix $M$ separately for a few overlapping ranges of the three-volume.
The effective action

The effective action obtained from the covariance matrix (4) is directly related to the effective transfer matrix $M$. The minisuperspace action (3) suggests that the effective transfer matrix given by

$$
\langle n|M|m \rangle = \mathcal{N} e^{-\frac{1}{T} \left[ \frac{(n-m)^2}{(n+m)^2} + \mu \left( \frac{n+m}{2} \right)^{\frac{3}{2}} - \lambda \frac{2n+m}{2} \right]}
$$

is a good approximation in the bulk where $n_t$ is large $^1$. Further, we will measure the empirical transfer matrix elements $\langle n|M|m \rangle$, extract the parameters $\Gamma$, $\mu$ and $\lambda$, and check that (12) is indeed a good approximation of the data. The measured effective transfer matrix $M$, for range $1200 < n_t < 1600$, is presented in Fig. 1 (left graph). The right graph shows the difference between the measured matrix $M$ and the best fit (12). Indeed, the difference disappears in the numerical noise proving that the approximation (12) is very good.

The measurements presented in this paper were performed for coupling constants $K_0 = 2.2$, $\Delta = 0.6$ and $K_4 = 0.922$.

4.1 The kinetic term

To get a better estimation of the parameters associated with the effective action (3) and (12), we first try to fit only the parameters of the kinetic term which is the dominating term from a numerical point of view. We do that by keeping the sum of the entries, i.e. $n + m$, fixed such that the potential term is not changing. In this way

---

$^1$ We slightly modified the form of the potential term. Such parametrization is more convenient to extract the parameters of the action.
we determine $\Gamma$ with high accuracy. The matrix elements for constant $n + m = c$ show the expected Gaussian dependence on $n$ (see Fig. 2),

$$\langle n|M|c-n\rangle = \langle n|M|c\rangle = \mathcal{N}(c) \exp\left[-\frac{(2n-c)^2}{\Gamma \cdot c}\right], \quad (13)$$

where the terms in the effective action which only depend on $c$ are included in the normalization.

We expect the denominator of the kinetic term $k(c)$ to behave like $k(n+m) = \Gamma \cdot (n+m)$. As shown in Fig. 3 this is indeed true and the parameter $\Gamma$ is constant in the whole range of the three-volumes. The best linear fit gives $\Gamma = 26.07 \pm 0.05$. 
This result is consistent with the values obtained from the fits for separate ranges of $n_t$.

### 4.2 The potential term

![Graph showing log($\langle n|M|n \rangle$) vs. $n$]

Fig. 4 $\log \langle n|M|n \rangle$ of the scaled transfer matrix (dots, different colors denote different ranges) compared with the fit of the potential term $-L_{eff}$ (red line, which stops at $n = 400$).

The potential part of the effective Lagrangian $L_{eff}$ may be extracted from the diagonal elements of the transfer matrix,

$$L_{eff}(n,n) = -\log \langle n|M|n \rangle + \text{const} = \frac{1}{\Gamma} \left( \mu n^{1/3} - \lambda n \right). \quad (14)$$

For technical reasons, we measured the transfer matrix $M$ separately for a few different ranges of the three-volume. Because, the normalization is not uniquely defined, in order to merge the effective Lagrangian, the constant in (14) has to be properly adjusted. The measured merged effective Lagrangian is shown in Fig. 4. The colors denote different ranges for which the transfer matrix was measured. Fig. 4 presents also the fit of form (14). In the bulk region, where $n_t$ is large enough, the theoretical expectation (14) fits very well. The measured values are $\mu = 16.5 \pm 0.2$ and $\lambda = 0.049 \pm 0.001$, where we took $\Gamma = 26.07$. Again, this result is consistent with the values obtained from the fits for separate ranges of $n_t$. 
5 Conclusions

The model of Causal Dynamical Triangulations comes with a transfer matrix \( \langle t_1 | H | t_2 \rangle \). The measured distributions of the three-volumes \( n_t \), e.g. \( P^{(T)}(n_t, n_{t+\Delta t}) \), have an exact definition in terms of the full transfer matrix \( H \) and the density matrix \( |n\rangle \langle n| \). The actual data coming from Monte Carlo simulations seem to allow for a much simpler description in terms of an effective transfer matrix \( M \), labeled by abstract vectors \( |n\rangle \) referring only to the three-volume. The effective transfer matrix \( M \) allows to directly measure the effective action \( S[n_t] \). An important advantage of the present method, since the number of slices \( T \) is small, is a much faster measurement of the transfer matrix compared to the covariance matrix, which was used previously to extract the effective action. Basically over the whole range of \( n_t \) the effective transfer matrix elements can be represented as

\[
\langle n | M | m \rangle = \mathcal{N} e^{\frac{1}{2} \left[ \left( \frac{n-m}{\Delta n/\Delta m} \right)^2 + \mu \left( \frac{n+m}{2} \right)^{1/3} - \lambda \frac{n+m}{2} \right]},
\]

with high accuracy. This result is fully consistent with the reduced minisuperspace action (3), although in CDT we do not freeze any degrees of freedom.

An issue not addressed in this article, is the problem of small three-volumes. For small \( n_t \) we do not observe a Gaussian distribution of the three-volume \( n_t \) around the mean value \( \langle n_t \rangle \). Because of strong discretization effects, the probability distributions, and consequently the effective transfer matrix elements, split into three families [6]. Despite different nature, after the smoothing procedure, the effective action for small volumes is basically the same as for large volumes, with a small modification in the potential [5]. It might be interpreted as possible curvature corrections, however, we are not able to measure it accurately in a discretization independent way.
